In this paper the results of DC conductivity investigation carried out for the polycrystalline *p*-terphenyl thin films, including temperature influence on the formation of the films, are presented. The conductivity measurements were done for the samples 1,7–12,5 μm thick with the polarizing voltages in the range 0–200 V at temperature varying from 15 to 325 K. The investigated thin films were supplied with gold and aluminium electrodes. The obtained results and their analysis indicate that the injection of charge from the electrodes into the area of the investigated material proceeds by field- and thermo-emission dependently on the temperature and electric field values. The charge transport through the material's bulk is controlled by traps present in the energy gap area (hopping mechanism and Poole-Frenkel phenomenon). The determined values of the activation energy are in the range of thermal energy (kT), which is equivalent to the none-activating hopping energy, close to 0,06 eV in the range of 15–200 K. In that temperature range conductivity of doping character is observed. In temperature varying from 200 to 325 K conductivity is metallic-like and the activation energy value is about 0,6 eV.
Key words: p-terphenyl, DC conductivity, organic semiconductors.

Polycrystalline films are characterized with many structural defects, which parturbate the material's internal potential so much that it influences its electrical conductivity. Changing the defects concentration it is possible to obtain samples with different electrical properties.

In the low ordered structures, instead of well defined energy gap, an area characterized with high density of traps exists. The Fermi level is placed near the center of the area and charge density wave functions overlap in a small degree. Therefore, energy diagrams of well compensated crystalline and polycrystalline semiconductors and amorfic materials are very similar. Polycrystalline materials are convenient objects for hopping conductivity investigations in a wide range of temperatures and electric fields. Deviations from the classical transport of thermally activated electrons that were observed in the low-ordered materials became a base for the hopping model with a variable range proposed by N.F. Mott in 1968 [1, 2, 6]. There are some problems with the determination of charge transport mechanism through such material's bulk going only on the $\ln\sigma = f(T^{-1/4})$ characteristics.

Even assuming that the traps distribution in the sample's bulk is homogenous and their activation energy changes linearly does not simplify the problem.

The physical properties of the investigated materials are crucial for the observed conductivity mechanism. Two- or three-dimensional hopping is observed dependently on:

1) how density of trap states changes with temperature,
2) what is dimensionality of the investigated sample, especially its thickness,
3) inhomogenities of the sample's bulk,
4) the existence of multiphoton processes,
5) the existence of Coulomb interaction during charge carriers transport (the influence of bulk on the value of current conducted in the material).

In high electric fields or in the case when the system electron-material is not an ideal injecting contact the current flowing through the sample is controlled by contact as well as bulk phenomena appearing in the material.

The subject of investigation reported here was p-terphenyl being one of the p-phenyl homologue row.

The material under investigation was scintillationally clean p-terphenyl, produced by FLUKA, of $C_{18}H_{14}$ stochiometry and molecular mass equal to 230,3101. The p-terphenyl molecule is flat and consists of three benzene rings lying in a straight line (fig. 1, a). The C-C bond length in benzene ring and between the rings is about $1,42 \cdot 10^{-10}$ and $1,48 \cdot 10^{-10}$ m, respectively. The p-terpehnyl crystal unit cell is monoclinic with the following crystallographic parameters: $a = 8,08 \cdot 10^{-10}$ m, $b = 5,6 \cdot 10^{-10}$ m, $c = 13,5 \cdot 10^{-10}$ m, $\beta = 91^{o}55'$ (fig. 1, b) [3–5].

The p-terphenyl samples used in the DC conductivity measurements was obtained as polycrystalline thin films. The samples were obtained through vacuum sublimation process on either BK–7 glass or gold substrate supplied with the gold electrodes. The sublimation process was controlled in regard of:

1) the rate of the layers growth;
2) the deposition process temperature
3) he pressure inside the chamber.

(gold)

Fig. 2, *a* presents a scheme of the thin films sublimation process together with the temperature check points. In fig. 2, *b* the system of electrodes and the way of giving the proper shape to the investigated material deposited on the glass substrate (BK–7) are presented.

The crystalline grains size present in the obtained thin films depended on sublimation process conditions, such as: the process temperature (in various part of sublimation chamber), the rate of *p*-terphenyl deposition and the type of substrate [5].
In fig. 3 and 4 the pictures of p-terphenyl thin films deposited on glass and gold substrate are presented. It is obvious that the size of crystalline grains of a thin film deposited on glass substrate depends on the *p*-terphenyl film thickness.

In fig. 3, *c*, 4, *c* and 5 it is seen that the size of crystalline areas is rather small and
those samples might be considered as nanocrystals. This was caused by the rate of heat
offtake from the "hot" *p*-terphenyl molecules which crystallized on gold substrate.
Fig. 5 is an evidence that the substrate type has significant influence on the *p*-terphenyl
polycrystal grains size. The width of the glass substrate in that case was about 35 μm.

The thickness of the investigated *p*-terphenyl polycrystalline films was in the range
1,5–15 μm. Measurements were consisted in evaluation of current flowing through the
sample bulk between the gold and aluminium electrodes. The measurements were

carried out for different electrodes polarities in the voltage range from 0 to 200 V in several temperatures changing from 15 to 325 K. Such wide range of temperatures was, to our knowledge, for the first time used in investigations of p-terphenyl thin films. The equipment used in the DC conductivity experiment was described in Ref. [5]. At the moment the equipment is fully computer controlled.

The results of the study of polycrystalline *p*-terphenyls thin films DC conductivity let us conclude that charge transport through the material's bulk is caused by various conductivity mechanisms. Character of the conductivity depends on the electric field value, temperature and electrodes polarities. The I–V characteristics shown in fig. 6 inform us about other than ohmic character of conductivity in the investigated material. Fig. 6, *a* and 6, *b* shows that switching of electrodes polarity does not change the shape of the I–V characteristics, i.e. does not influence the conductivity character. We can conclude that for the sample of 1,73 μm thick in a wide range of temperatures the sample behaves as a varistor and the conductivity is a bulk process (fig. 6, *a* and 6, *b*). Another sample, 6 μm thick, in a wide range of temperatures (16–260 K) the conductivity character does not depend on the electrodes polarity – the I–V characteristics are symmetrical – but the influence of the sample olarity is slightly seen. In the case of p-terphenyl 8,5 μm thick the conductivity character is like in semiconducting diode (fig. 6, *d*). When polarity is Au(-) we observe current flowing in conductivity direction while with polarity Au(+) the direction is damming. Such effect is observed in a wide range of temperatures (16–325 K).

Using the lnI=f(1/kT) relation (k- Boltzmann constant, T- temperature, I - current) we determined the DC conductivity energy for various sample polarizing voltages for the samples of different thickness. Typical lnI=f(1/kT) characteristics are shown in figure 7 [5, 6].

In each of lnI=f(1/kT) p-terphenyl characteristics it is possible to separate three areas with different slope. The slope magnitude is the measure of the activation energy for conductivity.

For example E_3 area in Fig. 7, *a* or E_2 in Fig. 7, *b* correspond to the energy of hopping conductivity through the localized states in the area of structural defects (lub barier jakichstam). The value of the activation energy for those mechanisms is of kT magnitude and was not shown in tables 1–5. The E_2 area seen in fig. 7, *b* characterises with the activation energy 0,01–0,06 eV in the temperature range 100–220 K. In this area the investigated material works like a semiconductor. The activation energy values greater tthan 0,1 eV but less than 0,7 eV correspond to metal-like conductivity. In fig. 8 the dependence of resistivity (R) of p-terphenyl thin film in respect to room temperature (R_t) was shown, T = 295 K. It is seen from the figure that the investigated material had semiconductor features below 80 K, while in temperature over 80 K behaved as metal.

a b

Fig. 9. The $\ln I = f(T^{-1/3})$ (a) and $\ln I = f(T^{-1/4})$ (b) curves obtained for polycrystalline p-terphenyl layers 2,45 μm thick; Au-Al electrodes

In low temperatures the transport of charge carriers, which concentration found from the $I = f(U^2/d^3)$ dependence was equal to $n = 0,4–0,5 \cdot 10^{22}$ m^{-3}, takes place through the hopping between localized states (the boundaries of crystalline grains) over the potential barriers separating the areas. An external electric field generated by the electrodes voltage lowers the barriers height, according to Poole – Frenkel low. In this case the hopping model is supported by rectilinear characteristics $\ln\sigma = f(T^{-1/3})$ and $\ln\sigma = f(T^{-1/4})$. It is evident (fig. 9) that we can consider two- and three- dimensional hopping [5–6]. Hopping mechanism is dominant in temperature below 120 K (fig. 9, a, 9, b).

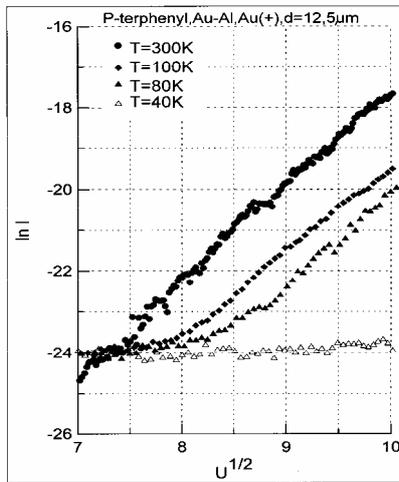

Fig. 10. lnI=f(U$^{1/2}$) dependence for – terphenyl layers 12,5 μm thick at ifferent temperatures; Au-Al electrodes, Au(+)
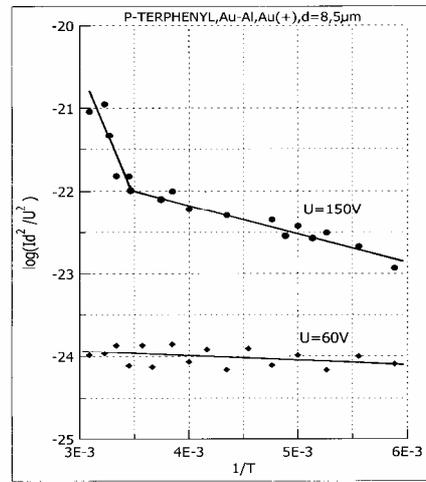

Fig. 11. log(Id^2/U^2)=f(1/T) ependence for p-terphenyl 8,5μm tthick Au-Al electrodes, Au(+)

While the external electric field increases the height of potential barrier near traps decreases (Poole-Frenkel effect) which makes the material's bulk involved into charge transport through the bulk. The Poole-Frenkel phenomenon is seen in via typical shape of $\ln I = f(U^{1/2})$ curve and lowering activation energy while supplied voltage increases (fig. 10). The presence of the phenomenon is also confirmed by the shape of the $\log(Id^2/U^2) = f(1/T)$ characteristics – fig. 11. The rectilinear section of the curves suggests that electric charge tunnels between bouded with structural defects trap states [5–6].

The injection of charge carriers from the electrodes to the investigated material bulk proceeds through thermo- and field emission. Figure 12 shows that high voltage determines injection of charge from an electrode to the p-terphenyl bulk in field emission (tunnelling) process and this phenomenon is dominant. This is a contact phenomenon confirmed additionally in fig. 13. It is seen that in the case of high electric field (U>60 V) Schottky phenomenon occurs as dominant. In the case of lower electric fields thermo-emission of charge from the electrodes to the sample's bulk is also important (fig. 12). The dependence shown in fig. 12 (Fowler-Nordheim curve)

illustrates contribution of the investigated material's surface and contact with the metal electrodes in the charge transport into the bulk [5].

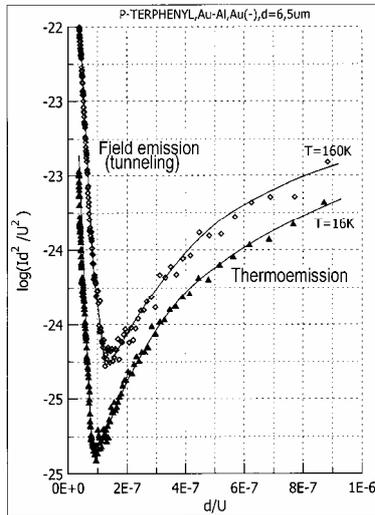

Fig. 12. Fowler-Nordheim plot $\ln(I/U^2)=f(1/U)$ for p-terphenyl layers 2,45 μm thick; Au-Al, Au(+)
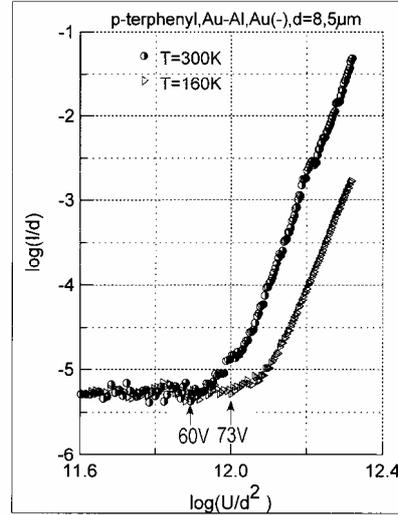

Fig. 13. $\log(I/d)=f[\log(U/d^2)]$ curve characteristic for Schottky phenomenon (rectilinear segments of the curves corresponding to higher voltage) taken at different temperatures.

1. There is more than one mechanism of conductivity in polycrystalline p-terphenyl films investigated in a wide range of temperatures and electric fields.
2. Electric charge injection from a metal electrode into the area of the investigated material occurs through the field emission (tunneling).
3. In high electric fields contribution of surface (metal electrode – p-terphenyl contact) is noticeable in charge transport through the sample bulk – Schottky phenomenon.
4. In high electric fields the Poole-Frenkel effect influences charge transport through the p-terphenyl bulk.
5. In low electric fields while temperature is less than 200 K the charge transport occurs through non-activated hopping (two- and three-dimensional), which is confirmed with small value of activation energy.

Запропоновано результати дослідження провідності за постійним струмом полікристалічних тонких плівок *p*-терфенилу та вплив температури на їх утворення. Вимірювання провідності проводили на зразках завтовшки 1,7–12,5 мкм з напругою поляризації 0–200 В при зміні температури від 15 до 325 К. Для досліджуваних тонких плівок використовувалися золоті та срібні електроди. Отримані результати засвідчують, що інжекційні зміни від електродів у ділянці досліджуваного матеріалу відбуваються завдяки авто- і термоемісії. Показано, що значення енергії активації є в межах теплової енергії, яка еквівалентна до неактиваційної енергії захоплення, близької до 0,06 еВ в області 15–200 К. За температури від 200 до 325 К енергія активації становить 0,6 еВ.

Ключові слова: p-терфенил, провідність за постійним струмом, органічні напівпровідники.

ЭЛЕКТРИЧЕСКАЯ ПРОВОДИМОСТЬ ПО ПОСТОЯННОМУ ТОКУ ПОЛИКРИСТАЛЛИЧЕСКИХ ПЛЕНОК *P*-ТЕРФЕНИЛА

С. Ткачик[1], И. Свионтек[1], И. Свионтек-Прокоп[2]

Предложены результаты исследования проводимости по постоянному току поликристаллических тонких пленок *p*-терфенила и влияние температуры на их образование. Измерения проводимости проводились на образцах толщиной 1,7–

12,5 мкм с напряжением поляризации 0–200 В при изменении температуры от 15 до 325 К. Для исследуемых тонких пленок использовались золотые и серебряные электроды. Полученные результаты удостоверяют, что инжекционные изменения от электродов в участке исследуемого материала происходят благодаря авто- и термоэмиссии. Показано, что значение энергии активации находится в пределах тепловой энергии, которая эквивалентна неактивационной энергии захвата, близкой к 0,06 eВ в области 15–200 К. При температуре от 200 до 325 К энергия активации составляет 0,6 eВ.
